Aim: Carotid-femoral pulse wave velocity is a well-known predictor of all-cause and cardiovascular mortality. Few studies have evaluated the relationship between brachial-ankle pulse wave velocity (ba-PWV) and coronary artery disease. We conducted this study to elucidate the relationship between arterial stiffness measured by ba-PWV and coronary atherosclerosis.

Methods: An automatic waveform analyzer was used to measure the ba-PWV. Multidetector computed tomography coronary angiography was used to assess the coronary artery calcium (CAC) score and to detect coronary stenosis. A total of 654 patients, including 358 women and 296 men (mean age, 54.5 ± 9.4 years), were recruited during the period March 2005 to June 2008.

Results: One hundred and twenty-seven patients (19.4%) had at least one stenotic coronary vessel. Mean ba-PWV and mean CAC scores were significantly higher in the stenotic group than in the normal control (15.94 ± 3.07 m/s vs. 14.39 ± 0.98 m/s; 293.1 ± 435.9 vs. 29.8 ± 110.8, respectively; both p < 0.001). The adjusted OR for coronary stenosis increased as ba-PWV increased (p for trend = 0.0001). Using ba-PWV < 14.0 m/s as the reference group, we found that ba-PWV between 14.0-18.0 m/s and ba-PWV > 18.0 m/s were significantly associated with coronary stenosis (OR, 2.48; CI, 1.56-3.93 and OR, 3.16; CI, 1.68-5.95, respectively). The cutoff point at 15.64 m/s using the ROC curve showed a sensitivity of 64.5%, specificity of 65.6%, and an AUC of 0.662 in predicting coronary artery stenosis. Ba-PWV had an additional power for correlating coronary artery disease with the Framingham risk score.

Conclusions: Ba-PWV correlated well with coronary atherosclerosis. Lifestyle modification is an efficacious therapeutic intervention for preventing the progression of arterial stiffness. This non-invasive technique can assist in the early detection of cardiovascular disease and should be included in community screening programs.

Key words: Atherosclerosis, Coronary artery disease, Pulse wave velocity

Introduction

Although the prevalence of coronary artery disease (CAD) has declined in the United States and in most European countries¹, CAD is still the leading cause of death in Taiwan². Arterial stiffness has been
shown to be associated with an increased risk of cardiovascular events\(^3,4\). Evaluation of arterial stiffness may assist in the early detection of atherosclerosis\(^5\). Pulse wave velocity (PWV) is an indicator of arterial stiffness and a marker of vascular damage\(^6-9\); however, in most of these studies, central PWV rather than peripheral PWV is normally used as an indicator of arterial stiffness\(^9\).

Multidetector row computed tomography (MDCT) is available in many general hospitals and enables accurate noninvasive assessment of coronary artery calcification (CAC) and stenosis\(^10,11\). Few studies have evaluated the relationship between peripheral arterial stiffness and CAD. We conducted this study to elucidate the relationship between brachial-ankle pulse wave velocity (ba-PWV) and coronary atherosclerosis using 64-slice MDCT in an asymptomatic general population.

**Methods**

**Study Subjects**

All of the 763 individuals that underwent a routine health examination for cardiovascular disease at the China Medical University Hospital during the period March 2005 to June 2008 were invited to participate in this study. Brachial-ankle PWV and coronary MDCT were included in the examination. Each participant was asked to complete a structured questionnaire designed to collect basic demographic data, medical history, and lifestyle characteristics.

Participants with a history of myocardial infarction, significant angina pectoris, significant cerebral vascular disease, or documented peripheral arterial disease were excluded from the study. They were all asymptomatic but with one or more risk factors of coronary heart disease. Of the 763 subjects who were invited, 21 patients did not complete the MDCT examination because of arrhythmia such as atrial fibrillation or other causes, 56 had cardiovascular diseases, and 32 did not sign the consent form; therefore, the final study population was composed of 654 individuals (296 men and 358 women; mean age, 54.5 ± 9.4 years).

**Measurement of Brachial-Ankle PWV Ankle-Brachial Pressure Index (ABI)**

Brachial-ankle PWV (baPWV) was measured using a volume-plethymographic apparatus (PWV/ABI; Colin Co., Ltd., Komaki, Japan) in accordance with previously described methodology\(^12,13\). This instrument records PWV, blood pressure in the four limbs, electrocardiogram, and heart sounds simultaneously. In all patients, baPWV was obtained after at least a 5-min rest in a supine position. The interobserver and intraobserver coefficients of variation for the measurement have been reported to be 8.4% and 10.0%, respectively\(^14\).

**Protocol of 64-Slice MDCT**

For assessments of calcium scoring, unenhanced cardiac CT was performed with a 64-detector row CT scanner (LightSpeed VCT; GE Medical System, Milwaukee, Wis) using prospective electrocardiography (ECG) triggering. The scanning range covered the entire heart from the level of the tracheal bifurcation to the diaphragm. The presence of calcification was determined according to the Agatston method\(^15\) for multi-detector row CT with a 130-HU threshold using a computer workstation (Card IQ, Advantage Workstation 4.3; GE Medical System). The vessel and CAC scores were independently determined by two radiologists and were averaged. The intra-assay coefficient of variation for the scoring was <5%.

Contrast-enhanced CT coronary angiography was performed with the same 64-detector row CT scanner using retrospective ECG-gating in a single breath hold. A 70-mL bolus of Iohexol (Omnipaque 350, 350 mg I/mL; GE Healthcare Ireland, Cork, Ireland) or Ioversol (Optiray 350, 350 mg I/mL; Tyco Healthcare, Montreal, Quebec, Canada) followed by 40 mL saline solution was continuously injected into an antecubital vein through an 18-gauge catheter at an injection rate of 5 mL/s. Transverse images were transferred to a computer workstation (Card IQ, Advantage Workstation 4.3; GE Medical System) for image post-processing. Two experienced observers ranked the image quality using a three-point ranking scale and analyzed all CT scans for signs of stenosis. In cases of disagreement between the two observers, a final decision was reached by consensus. Significant coronary stenosis was defined as a lumen diameter reduction of greater than 50% in any segment.

**Clinical and Laboratory Examinations**

The clinical examination included measurement of sitting blood pressure (with a random -zero sphygmomanometer), height, and weight. On the morning of the health examination, an overnight fasting blood sample was collected prior to the electron beam CT and brachial-ankle pulse wave velocity measurement. The blood samples were analyzed for the following parameters using standard techniques with commercial kits: total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, triglyceride, glucose, uric acid, and high-sensitivity
C-reactive protein (hs-CRP). The prediction of coronary heart disease was calculated using the Framingham risk score (FRS)\(^6\).

### Statistical Analysis

All data are expressed as the mean ± SD. Pearson correlation coefficients were used to assess the linear relationship between ba-PWV and the coronary artery calcium score. Differences in each variable between any two groups were evaluated using the \( t \)-test for continuous variables and the chi-square test for categorical variables. Because the distribution of the CAC scores was highly skewed, the common log-transformed CAC score \[\log (\text{CAC score} + 1)\] was used for further analysis. Comparisons of continuous data among three groups were based on analysis of variance (ANOVA). Multivariate logistic regression analysis was used to test the explanatory effect of each independent variable. The significant effect of each variable was determined by Wald statistics. Receiver operating characteristic (ROC) curves for coronary stenosis and ba-PWV, CAC score, and FRS were constructed and the area under the curve (AUC) was calculated. All of the analyses were conducted using the SAS software package for Windows, version 9.13. (SAS institute Inc., Cary, NC). \( P \) values of \(< 0.05\) were considered significant.

We confirm that all applicable institutional and governmental regulations concerning the ethical use of human volunteers were followed during this research. Ethics approval for patient recruitment and analysis of data was obtained from the Institutional Review Board of the China Medical University Hospital in Taiwan.

### Results

The 10-year risk of coronary artery disease calcu-
lation using the Framingham risk score showed that 70% of the subjects were in the low-risk group, 20% in the moderate-risk group, and only 10% of the subjects were in the high-risk group. Of the 654 study subjects, 127 (19.4%) were diagnosed as having at least one significant coronary stenotic lesion.

Table 1 shows the basic characteristics of the normal controls and the subjects with coronary artery stenosis. The stenotic group had a higher mean age, body mass index, waist circumference, blood pressure, glucose level, and a higher proportion of men than the control group. There were no differences in total cholesterol, triglyceride levels or ankle-brachial pressure index (ABI) between the 2 groups; however, HDL-cholesterol was significantly lower in the stenotic group than in the control group. In addition, mean ba-PWV and the CAC score were significantly higher in the stenotic group than in the normal control group (15.94 ± 3.07 m/s vs. 14.39 ± 0.98 m/s; 293.1 ± 435.9 vs. 29.8 ± 110.8, respectively; both p < 0.001).

The age- and sex-adjusted OR for coronary artery stenosis was significantly higher in subjects with BMI ≥ 27 kg/m² (OR, 2.77; 95% CI, 1.63-4.69) and central obesity (OR, 1.73; 95% CI, 1.17-2.56) (Table 2). As expected, hypertension and diabetes mellitus were significantly associated with coronary stenosis (OR, 3.98; 95% CI, 2.58-6.13 and OR, 1.71; 95% CI, 1.04-2.80, respectively). The adjusted OR for coronary stenosis increased as ba-PWV increased (p for trend = 0.0001). Using ba-PWV < 14.0 m/s as the reference group, we found that ba-PWV between 14.0-18.0 m/s and ba-PWV > 18.0 m/s were significantly associated with coronary stenosis (OR, 2.48; 95% CI, 1.56-3.93 and OR, 3.16; 95% CI, 1.68-5.95, respectively) (Table 3). Pearson correlation analysis revealed that ba-PWV was significantly correlated with CAC score (r = 0.4, p < 0.001), which increased as the ba-PWV increased. The mean CAC score was 35.7 ± 173.6 for ba-PWV < 14.0 m/s, 100.2 ± 249.7 for ba-PWV between 14.0-18.0 m/s, and 227.6 ± 412.5 for ba-PWV > 18.0 m/s (p < 0.001, ANOVA).

Using the ROC curve, we determined the optimal cutoff value of ba-PWV and CAC score that could predict the presence of coronary stenosis (Fig. 1). The cutoff value of ba-PWV at 15.64 m/s had a sensitivity of 64.5%, specificity of 65.6%, and an AUC of 0.662 in predicting coronary artery stenosis. The cutoff value of the CAC score of 9.6 had a sensitivity of 80.0%, specificity of 79.9%, and an AUC of 0.853 in predicting coronary stenosis. We further analyzed the 10-year risk of coronary heart disease calculated by the Framingham risk score (FRS). The cutoff point of FRS at 11.8% curve showed a sensitivity of 67.0%,
specificity of 71.1%, and an AUC of 0.676. After combining FRS and ba-PWV, the AUC of the ROC curve increased to 0.728. Ba-PWV had an additional power for correlating CAD to the Framingham risk score.

**Discussion**

Pulse wave velocity is an established index for arterial stiffness. In the present study, we demonstrated that ba-PWV correlated well with coronary atherosclerosis and stenosis in asymptomatic patients.

A few studies have addressed the relationship between ba-PWV and CAD in patients with suspected CAD or CAD equivalent. Tsuchiya M *et al.* found that stiffness in lower-leg arteries is associated with the severity of coronary calcification among asymptomatic type 2 diabetic patients. A cutoff point of ba-PWV at 18.0 m/s is a diagnostic value for identifying patients with the highest CAC score. Kim *et al.* revealed that ba-PWV at 16.35 m/s had a sensitivity of 73% and specificity of 75% in detecting multiple coronary artery disease in Korean patients with diabetes. Imanishi R *et al.* revealed that a high ba-PWV level (mean: 18.9 m/s vs. 15.2 m/s) is an independent predictor of the presence of CAD in men with suspected heart disease. Xu *et al.* showed that in suspected CAD patients, a ba-PWV > 18.0 m/s often follows a severe coronary event. Our study revealed that in asymptomatic patients, ba-PWV at 15.64 m/s had a sensitivity of 64.5%, specificity of 65.6%, and an AUC of 0.662 in predicting coronary artery stenosis. A similar result was found by Koji Y *et al.* in an asymptomatic Japanese population. These results indicate that the cutoff point of ba-PWV for detecting CAD may be lower in asymptomatic persons that in
patients with suspected CAD or CAD equivalent.

The area under the ROC curve in this cross-sectional study indicates that the CAC score was better than ba-PWV in predicting the presence of CAD in asymptomatic patients. The values depicting the area under the ROC curve for ba-PWV were somewhat moderate in significance. A similar finding was reported by Tanaka et al.,23 The reason may be related to a lower cardiovascular risk in the Asian population. Further prospective longitudinal studies are warranted to properly address this issue.

Assessment of central arterial stiffness rather than peripheral arterial stiffness is more relevant to CAD risk stratification.6, 24 Carotid-femoral PWV is the gold standard for assessing central arterial stiffness,25 however, a high level of skill and exposure of the inguinal region are required for the measurement and its applicability is limited. The method we used is simple enough to use in clinical practice and community screening. A limitation of measuring the ba-PWV is that this parameter reflects not only elastic arterial stiffness but also muscular arterial stiffness.10 Nonetheless, ba-PWV and carotid-femoral PWV have both been shown to be associated with cardiovascular disease risk factors and clinical events.23 Recently, Tsuchikara S et al. also reported that ba-PWV is an index of central arterial stiffness showing similar characteristics to those of central aortic PWV.26 Yu et al. reported that ba-PWV correlates better with LV mass and diastolic function and other indices of arterial function than carotid-femoral PWV, probably because ba-PWV encompasses a greater territory of the arterial tree than carotid-femoral PWV.27

Multislice computed tomography angiography is a non-invasive technique that can reliably detect coronary stenosis and quantify the degree of calcified plaque burden.28 Diffuse noncalcified plaques, which may result in blurred contours of the contrast-enhanced lumen, and small noncalcified plaques were not included in this analysis; therefore, the presence of noncalcified plaques will be underestimated compared with histologic postmortem studies.

In our study, a similar distribution of demographic characteristics between participants and nonparticipants was found, indicating a random-type selection error. Thus, the biased results of the effect may be toward the null, indicating a lower threat to validity.

In conclusion, the present study revealed that arterial stiffness measured by ba-PWV correlated well with coronary atherosclerosis in a general population in Taiwan. Lifestyle modification, such as aerobic exercise and sodium restriction, is reported to be an efficacious therapeutic intervention for preventing the progression of arterial stiffness.29 This non-invasive technique can assist in the early detection of cardiovascular disease and should be included in community screening programs.
